We have investigated the polarization entanglement between photon pairs generated from a biexciton in a CuCl single crystal via resonant hyper parametric scattering. The pulses of a high repetition pump are seen to provide improved statistical accuracy and the ability to test Bell's inequality. Our results clearly violate the inequality and thus manifest the quantum entanglement and nonlocality of the photon pairs. We also analyzed the quantum state of our photon pairs using quantum state tomography.

Recently, the issue of “quantum entanglement” has been attracting the interest of many researchers, because this property acts as an essential principle in quantum info-communication (QIC) technologies. The first reliable source that experimentally manifested the entanglement was cascaded two-photon emission from a single atom, such as calcium [1, 2, 3, 4] and mercury [5, 6]. In this scheme, the change in the atom's total angular momentum is transferred to the photon pair, so that the photons' polarizations, i.e., internal angular momenta, are entangled. Aspect *et al.* [3, 4] demonstrated the polarization entanglement of photons generated from a calcium atomic cascade by testing Clauser, Horne, Shimony and Holt (CHSH) type Bell's inequality [7]. The other popular method to generate polarization-entangled photons is to use spontaneous parametric down-conversion (SPDC) [8, 9]. The phase-matching condition concerned with macroscopic coherence of the optical waves is essential to generate the entanglement in SPDC. In order to proceed in the development of QIC, semiconductor sources of entangled photons are highly desired. Cascaded two-photon emission from a biexciton, semiconductor analogue of the atomic cascade, is a promising method to generate polarization-entangled photons [10]. Recently, we demonstrated for the first time entangled photon generation from a semiconductor material [11]. We used biexciton-resonant hyper parametric scattering (RHPS) [12, 13] in a CuCl crystal. The RHPS, or two-photon resonant Raman scattering, in CuCl has been thoroughly investigated in view of classical spectroscopy [14, 15]. Most recently, the generation of entangled photons from semiconductor quantum dots has been also reported [16, 17, 18].

In this letter, we report that highly polarization-entangled photon pairs can be obtained with time correlation histograms of enhanced visibility by using a high repetition rate (1 GHz) pump light system. Based on the results of polarization correlation measurements, we show that Bell's inequality has been clearly violated. Fur-

thermore, we quantitatively analyze the quantum state of the observed photon pairs utilizing quantum state tomography [19, 20].

In RHPS, like in SPDC, the photons concerned must satisfy the phase-matching condition. In SPDC, the birefringence of the nonlinear crystal allows photons to satisfy this condition. On the other hand, in RHPS, the dispersion relation of the exciton polariton is important for the phase-matching condition, as shown in Fig. 1. In RHPS, two pump-photons are resonantly absorbed and create a biexciton in a semiconductor material. The created biexciton then decays coherently into two daughter photons. The difference of RHPS from SPDC is that the process includes a resonant effect, making RHPS more efficient than SPDC, although RHPS is a higher order ($\chi^{(3)}$) nonlinear process than SPDC ($\chi^{(2)}$). The formation mechanism of polarization entanglement is quite

FIG. 1: Dispersion relation of exciton polariton (shaded surface) and phase matching condition of RHPS (red and black curves: the latter is the projection of the former to the k_x - k_z plane) in two-dimensional k -space. In our case, the wave vector pump light is in parallel with the k_z axis, and the k_x - k_z plane corresponds to the parallel plane of laboratory system in real space. The green arrows indicate the wave vectors of HEP, LEP, and two pump photons.

similar to that of a two-photon cascade emission from a calcium atom [3, 4]. That is, the total angular momentum J of the initial state (lowest biexciton) is $J = 0$ and those of the two final states (HEP and LEP) are $J = 1$. Here, HEP and LEP represent a high energy polariton and a low energy polariton, respectively. Taking account of the dipole interaction between an exciton and a photon, the polariton pair are in the entangled angular momentum state

$$\frac{1}{\sqrt{2}}(|+1, -1\rangle + |-1, +1\rangle), \quad (1)$$

where the first and second symbols in the ket vectors represent the z-component of J for HEP and LEP, respectively. Here, we assume that the wave vectors of the two polaritons are parallel to each other. Therefore, the emitted photon pair from HEP and LEP are in the maximally-entangled polarization state

$$\begin{aligned} |\Psi\rangle &= \frac{1}{\sqrt{2}}(|R_1 L_2\rangle + |L_1 R_2\rangle) \\ &= \frac{1}{\sqrt{2}}(|H_1 H_2\rangle + |V_1 V_2\rangle) \\ &= \frac{1}{\sqrt{2}}(|D_1 D_2\rangle + |\bar{D}_1 \bar{D}_2\rangle), \end{aligned} \quad (2)$$

where R_i and L_i denote right and left circular polarization, H_i , V_i , D_i and \bar{D}_i denote horizontal (0°), vertical (90°), 45° and -45° linear polarization, respectively.

The sample used in our experiment is a vapor-phase grown CuCl single crystal having a slab-like shape (thickness: approx. $100 \mu\text{m}$). The temperature of the sample was kept at 4 K in a cryostat. Figure 2 shows our experimental setup. The pump light was the second harmonic light of a femtosecond mode-locked Ti:Sapphire laser having a 1 GHz repetition rate. The pump light was then spectrally filtered by a zero-dispersion double monochromator. The wavelength of the pump light was set to be in the two-photon resonance with the lowest biexciton. The output light from the monochromator

FIG. 3: RHPs spectra in CuCl single crystal. The central peak indicates the Rayleigh scattered pump light, and this energy is tuned at two-photon resonance with the biexciton (3.186 eV). Spectral bandwidth of the pump laser was set to 0.3 nm. The two side peaks around the central peak are the RHPs signals of HEP and LEP. The small peak labeled as I_1 is the emission of the bound exciton. The two peaks (M_T , M_L) on the lower energy side are the emission from the biexciton leaving the transverse and longitudinal excitons, respectively.

passes through an ND filter, and is focused on the sample. In order to suppress the accidental coincidence of uncorrelated photons, as described below, we had to reduce the pump power to around $10 \mu\text{W}$. The emitted photons from the sample are fed into the optical multi-mode fibers connected to the two monochromators. The angle between the pump light and the emitted photons was approximately 45° . In this condition, the angle between the wave vectors of HEP and LEP inside the crystal was 29° . Using the polarization analyzers consisting of a $\lambda/4$ plate and a polarizer in front of the fiber, we measured the polarization state of each photon. Monochromators (1) and (2) select the HEP and LEP photons from the pump laser and the other emissions (see Fig. 3). The photons are detected by two photomultipliers, and the time-interval analyzer records the difference in arrival time between the photons.

Figure 4 shows the results of the polarization correlation measurements using three different polarization bases, i.e., R - L , H - V , and D - \bar{D} . In these results, the coincidence signals at $\tau = 0$ clearly appear only in the RL , LR , HH , VV , DD , and $\bar{D}\bar{D}$ polarization combinations. These results indicate that the observed photon-pairs have polarization-correlation as predicted in Eq. (2). It is noteworthy that the signal to noise ratio (S/N) between the coincidence signals and the uncorrelated background ($\tau \neq 0$) was quite high; in the present study, the S/N was approximately 20. In contrast, in the experiment described in our previous report [11], the background had a significant effect on correlated photon signals (S/N ~ 2), so that the background was subtracted from the coincidence signal. In presenting the evidence of the entanglement, this subtraction is an allowable correction. However, this is not applicable to practical use as an en-

FIG. 4: Time correlation histograms between the HEP and LEP for the three polarization basis (H - V , D - \bar{D} , R - L). The central peak at $\tau = 0$ is the correlated two-photon coincidence signal originating from one biexciton. The background signal at $\tau \neq 0$ results from the uncorrelated photons.

tangled photon source in QIC. When the pump power is high, an accidental coincidence of two photons generated from two biexcitons is the main origin of the background. In this case, the accidental coincidence is quadratically proportional to the number of signal photons generated per pump pulse. Thus, the background can be suppressed by the reduction of the pump energy per pulse. Thanks to the high repetition rate of the pump laser, we were able to suppress the background while keeping the total number of the signal photons, as in the data shown in Fig. 4. Note that, in the following, we analyze the data without artificial subtraction of the background.

Using these data with negligibly small background, the violation of Bell's inequality is demonstrated to show the non-local nature of the state of our entangled photon pair. According to CHSH theory [7], the inequality can be written as

$$S = |E(\theta_1, \theta_2) - E(\theta'_1, \theta_2) + E(\theta'_1, \theta'_2) + E(\theta_1, \theta'_2)| \leq 2, \quad (3)$$

and $E(\theta_1, \theta_2)$ is given by

$$E(\theta_1, \theta_2) = \frac{C(\theta_1, \theta_2) + C(\theta_1^\perp, \theta_2^\perp) - C(\theta_1^\perp, \theta_2) - C(\theta_1, \theta_2^\perp)}{C(\theta_1, \theta_2) + C(\theta_1^\perp, \theta_2^\perp) + C(\theta_1^\perp, \theta_2) + C(\theta_1, \theta_2^\perp)}, \quad (4)$$

where $C(\theta_1, \theta_2)$ is the coincidence count for each polarization angle and $\theta_i^\perp \equiv \theta_i + 90^\circ$. Table I represents the result of coincidence counts $C(\theta_1, \theta_2)$ recorded for 16 combinations of analyzer setting ($\theta_1 = 0^\circ, 45^\circ, 90^\circ, 135^\circ$; $\theta_2 = 22.5^\circ, 67.5^\circ, 112.5^\circ, 157.5^\circ$). From this result, we can obtain the S -value of $2.34 \pm 0.1 > 2$. It is clear that the S -value apparently violates Bell's inequality by more than 3 times the standard deviation.

Although the obtained S -value violates Bell's inequality, the obtained S -value was smaller than the ideal S -value $2\sqrt{2}$ derived from Eq. (2). To fully characterize the

quantum state of the observed photon pairs, quantum state tomography was performed to reconstruct the density matrix of the two-photon polarization state [19, 20]. For this analysis, 22 independent polarization correlation data including those in Fig. 4 were used. Figure 5 shows the density matrix thus obtained. In this density matrix, the two off-diagonal elements, $|H_1 H_2\rangle \langle V_1 V_2|$ and $|V_1 V_2\rangle \langle H_1 H_2|$, together with the two diagonal elements, $|H_1 H_2\rangle \langle H_1 H_2|$ and $|V_1 V_2\rangle \langle V_1 V_2|$, clearly appear, while other elements are almost negligible. The shape of this density matrix is essentially identical to that expected from Eq. (2), in which the two off-diagonal elements represent the coherence between the two-photon polarization states of $|V_1 V_2\rangle$ and $|H_1 H_2\rangle$. Based on this reconstructed density matrix ρ , we estimated the value of fidelity, $F \equiv \langle \Psi | \rho | \Psi \rangle$, as 0.85, which is much larger than the classical limit of 0.5. To quantitatively characterize the degree of disorder and degree of entanglement of the photon-pair [21], we also calculated the linear entropy (S_L) and the tangle (T) from the density matrix. The value of the entanglement of formation (EOF) was also derived from T . The calculated values are $(S_L, T, EOF) = (0.31, 0.56, 0.65)$.

In the reconstructed density matrix, the element of $|H_1 H_2\rangle \langle H_1 H_2|$ is larger than that of $|V_1 V_2\rangle \langle V_1 V_2|$, al-

$\theta_2 \backslash \theta_1$	0°	45°	90°	135°
22.5°	134	106	19	44
67.5°	43	107	81	18
112.5°	13	27	85	80
157.5°	104	20	34	143

TABLE I: Coincidences counts $C(\theta_1, \theta_2)$ for different polarizer angles used in the CHSH inequality test. They correspond to the integration counts of peak area in 300 seconds.

FIG. 5: Reconstructed two-photon polarization density matrix for the photon pairs generated from RHPS.

though they should be identical based on the ideal maximally entangled state (2). This discrepancy occurs for the following two reasons. One is the geometrical polarization selection rule in the RHPS process [14, 15, 22], which is unavoidable when the photon pairs are detected at finite angles. The other is the difference in the transmittance at the sample surface (between H and V polarized photons) due to Fresnel formula. Because of the above, the two-photon polarization state of emitted photon pairs as seen in the sample is written as

$$|\Psi_\epsilon\rangle = \frac{1}{\sqrt{\epsilon^2 + 1}}(\epsilon|H_1H_2\rangle + |V_1V_2\rangle), \quad (5)$$

which is a non-maximally entangled pure state [19]. In our case, ϵ is expected to be 1.19. Furthermore, we should take account of the mixture of the uncorrelated photons. Thus, the density matrix of the observed two-photon polarization state is described as

$$\rho_f = \frac{\gamma}{4}I + (1 - \gamma)|\Psi_\epsilon\rangle\langle\Psi_\epsilon|, \quad (6)$$

where γ is the degree of contribution of the mixed state. In our case, it is estimated as $\gamma = 0.15$. With these parameters, the value of fidelity, $F \equiv |\sqrt{\rho_f}\rho\sqrt{\rho_f}|^2$, was estimated as 0.94; the density matrix ρ_f reproduces most of the features of the density matrix ρ reconstructed from the observed results.

We have succeeded in obtaining entangled photons via RHPS by using a pump light with a high repetition rate. The high visibility coincidence data clearly shows the polarization correlation. From these data, we reconstructed a density matrix using quantum state tomography. The density matrix shows that the observed photon pairs are highly entangled and agree with the results of our theoretical model. In addition, we demonstrated the violation of Bell's inequality in regard to the entangled photons generated from a semiconductor. RHPS using a semiconductor can be employed as a practical QIC device, acting as an entangled photon source.

The authors thank M. Hasegawa for his help in preparing samples. They are grateful to Professors T. Itoh, H. Ishihara, H. Ohno, H. Kokasa, and Dr. Y. Mitsumori for

their valuable discussion.  - [22] Degree of polarization of the RHPS signal is given by $D(\beta) \equiv (I_V - I_H)/(I_V + I_H) = \left(\frac{2}{\sin^2 \beta} - 1\right)^{-1}$, where I_V and I_H are the count of V and H polarized photons of HEP or LEP, respectively, β is the angle between the wave vector of HEP and LEP in the sample. Therefore, the two photon polarization state via RHPS becomes $|\Psi(\beta)\rangle = (\sqrt{1 - D(\beta)}|H_1, H_2\rangle + \sqrt{1 + D(\beta)}|V_1, V_2\rangle)/\sqrt{2}$. In our case, $\beta \approx 29^\circ$, $D \approx 1.4$.
